Keeling Curve

“Keeling” redirects here. For other uses, see Keeling (disambiguation).

The Keeling Curve is a graph which plots the ongoing change in concentration of carbon dioxide in Earth’s atmosphere since 1958. It is based on continuous measurements taken at the Mauna Loa Observatory in Hawaii that began under the supervision of Charles David Keeling. Keeling’s measurements showed the first significant evidence of rapidly increasing carbon dioxide levels in the atmosphere. Many scientists credit Keeling’s graph with first bringing the world’s attention to the current increase of carbon dioxide in the atmosphere. [1]

Charles David Keeling, of Scripps Institution of Oceanography at UC San Diego, was the first person to make frequent regular measurements of the atmospheric carbon dioxide (CO₂) concentration, taking readings at the South Pole and in Hawaii from 1958 onwards. [2]

Prior to Keeling, the concentration of carbon dioxide in the atmosphere was thought to be affected by constant variability. Keeling had perfected the measurement techniques and observed “strong diurnal behavior with steady values of about 310 ppm in the afternoon” at three locations: (Big Sur near Monterey, the rain forests of Olympic Peninsula and high mountain forests in Arizona). [3] By measuring the ratio of two isotopes of carbon, Keeling attributed the diurnal change to respiration from local plants and soils, with afternoon values representative of the “free atmosphere”. By 1960, Keeling and his group had determined that the measurement records from California, Antarctica, and Hawaii were long enough to see not just the diurnal and seasonal variations, but also a year-on-year increase that roughly matched the amount of fossil fuels burned per year. In the article that made him famous, Keeling observed, “at the South Pole the observed rate of increase is nearly that to be expected from the combustion of fossil fuel”. [4]

1 Mauna Loa measurements

Due to funding cuts in the mid-1960s, Keeling was forced to abandon continuous monitoring efforts at the South Pole, but he scraped together enough money to maintain operations at Mauna Loa, which have continued to the present day [5] alongside the monitoring program by NOAA. [6]

The measurements collected at Mauna Loa show a steady increase in mean atmospheric CO₂ concentration from about 315 parts per million by volume (ppmv) in 1958 to 401 ppmv as of April 2014. [7][8] This increase in atmospheric CO₂ is considered to be largely due to the combustion of fossil fuels, and has been accelerating in recent years. Since carbon dioxide is a greenhouse gas, this has significant implications for global warming. Measurements of carbon dioxide concentration in ancient air bubbles trapped in polar ice cores show that mean atmospheric CO₂ concentration has historically been between 275 and 285 ppmv during the Holocene epoch (9,000 BCE onwards), but started rising sharply at the beginning of the nineteenth century. [9]

Keeling and collaborators made measurements on the incoming ocean breeze and above the thermal inversion layer to minimize local contamination from volcanic vents. In addition, the data are normalized to negate any influence from local contamination. [10] Measurements at many other isolated sites have confirmed the long-term trend shown by the Keeling Curve, [11] though no sites have a record as long as Mauna Loa. [12]

The Keeling Curve also shows a cyclic variation of about 5 ppmv in each year corresponding to the seasonal change in uptake of CO₂ by the world’s land vegetation. Most of
this vegetation is in the Northern hemisphere, since this is where most of the land is located. From a maximum in May, the level decreases during the northern spring and summer as new plant growth takes carbon dioxide out of the atmosphere through photosynthesis. After reaching a minimum in October, the level rises again in the northern fall and winter as plants and leaves die off and decay, releasing the gas back into the atmosphere.\[^{[13]}\]

Due in part to the significance of Keeling’s findings\[^{[5]}\] the NOAA began monitoring CO\(_2\) levels worldwide in the 1970s.\[^{[6]}\] Today, CO\(_2\) levels are monitored at about 100 sites around the globe.\[^{[1]}\]

Carbon dioxide measurements at the Mauna Loa observatory in Hawaii are made with a type of infrared spectrophotometer called a capnograph by, John Tyndall, its inventor in 1864, but now known as a nondispersive infrared sensor.\[^{[14]}\] Currently (May, 2013) several laser-based sensors are being added to run concurrently with the IR spectrophotometer at Scripps, while NOAA measurements at Mauna Loa use nondispersive infrared sensor tightly calibrated using WMO standards as the main reference for the curve.\[^{[15]}\] Multiple other sensors and technologies are also used at Mauna Loa to augment these measurements.

Keeling died in 2005. Supervision of the measuring project was taken over by his son, Ralph Keeling, a professor of geochemistry at Scripps Oceanography.\[^{[16]}\]

When C.D. Keeling published his 1960 paper, there did not appear to be any evidence of oceanic absorption. Keeling conjectured that this might be attributable to fluctuations in the causation of the seasonal variation, within the small number of years since his measurements had begun. However it is now understood that allowance should be made for about 50% absorption by the oceanic sinks.\[^{[17]}\] Keeling father and son have contributed to the work which has since yielded a much fuller understanding of the relation between atmospheric CO\(_2\) and the entirety of the carbon cycle, including the effects of land and ocean sinks.\[^{[18]}\]

On May 9, 2013, the daily mean concentration of carbon dioxide in the atmosphere measured at Mauna Loa surpassed 400 parts per million (ppm) for the first time since measurements began in 1958.\[^{[19]}\]
